## A toy model of neural integrator

An animal moves on a one-dimensional track. In order to navigate properly (e.g., to find its way back home) the brain must compute the 'on line' position of the animal given sensory information about its velocity. We will assume that the position is computed by means of a network composed of two neurons, whose input is the animals velocity. The network obeys the following equations:

$$\begin{aligned}\tau \frac{dx}{dt} &= -ax - 2y + \tau V(t); \\ \tau \frac{dy}{dt} &= -(3-a)x - y - \tau V(t)\end{aligned}\tag{1}$$

where the value of  $x(t)$  represents the estimated position of the animal at time  $t$ .

(a) Study the dynamics of the network for constant velocity, i.e.,  $V(t) = V_0$  for all  $t > 0$ : First, find the fixed point of the network and the region of values of the parameter  $a$  for which this fixed point is stable. Next, write down the solution for  $x(t)$  given that  $(x(0), y(0)) = (0, 0)$  and explain what happens as time increases.

(b) Position Estimation. Assume that at  $t = 0$ , the animal starts out at the origin, and begins moving at a constant velocity  $V(t) = 0.1$  m/s. Use  $\tau = 100$  ms. If the system acted as a perfect integrator of the velocity, the expected position at  $t = 10$  s would be 1 m. Is there a parameter choice (for parameter  $a$ ) for which this system acts as a perfect integrator? (If so, take any appropriate limits to prove it.) For what range of parameters does the system act as a leaky integrator, i.e., the readout is within 1 cm error of the estimated position from a perfect integrator after 10 seconds? What happens to  $x(t)$  when  $a$  is outside this range?

## Backpropagation rule

Derive the backpropagation rule for 3-layer networks. Suppose for the neurons, we use the following notations:

$$I_j^i = b_j + \sum_k r_k^{i-1} w_{jk} \quad (2)$$

$$r = \frac{1}{1 + e^{-I}} \quad (3)$$

The superscript denotes which layer and subscript denotes which neuron in the layer. Please write out the equations for the value on the final third layer and take the gradient and show why backpropagation algorithm works.

## Hopfield model

In the Hopfield network, we make even a more drastic assumption that the activity of a neuron is a binary variable,  $s_i \in [+1, -1]$ . In the deterministic version of this model, the state of a cell is set according to the following equation

$$s_i(t + \Delta t) = \mathbf{sgn}\left(\sum_j w_{ij} s_j\right), \quad (4)$$

We consider an asynchronous update rule for each neuron (choosing either a random or fixed update order and update  $s_i$  according to that order at each clock cycle).

(1) Check my lecture note and proof that any mixture of an odd number of memory patterns, such as

$$\xi^{mix} = \text{sign}(\xi^{\mu_1} + \xi^{\mu_2} + \xi^{\mu_3}) \quad (5)$$

are fixed point of the Hopfield model.

(2) Numerically simulate the dynamics of Hopfield network with random unbiased memory patterns, using 500 binary neurons. We want to draw some statistical conclusions, so in the tasks that follow, you should run many simulations using different sets of random stored patterns and, for each, start from many different initial conditions (so I recommend writing reasonably efficient routines, e.g. minimize the number of for-loops in MATLAB). For simplicity, you can choose the order of update of the neurons by going through neuron 1 to  $N$  all the time.

i) Probability of perfect recall: Store 10 patterns, run simulations to find the probability of perfect recall. That is, start with a pattern, corrupt some fraction of its bits, input the corrupted pattern to the network, and wait until the network settles into a fixed point. Plot the fraction of times you get perfect

recall of the original state against the fraction of corrupted bits.

ii) Memory retrieval with errors: Start the dynamics with one of the memory states. Plot the fraction of errors (fraction of incorrectly recalled bits) in the final state as a function of the number of stored patterns  $P$ . Change  $P$  from 10 to 100.
